Abstract

We study isomorphism invariant point processes of \mathbb{R}^d whose groups of symmetries are almost surely trivial. We define a 1-ended, locally finite tree factor on the points of the process, that is, a mapping of the point configuration to a graph on it that is measurable and equivariant with the point process. This answers a question of Holroyd and Peres. The tree will be used to construct a factor isomorphic to \mathbb{Z}^n . This perhaps surprising result (that any d and n works) solves a problem by Steve Evans. The construction, based on a connected clumping with 2^i vertices in each clump of the i 'th partition, can be used to define various other factors.

1. Introduction

A point process on \mathbb{R}^d is, intuitively, a random discrete set of points scattered in \mathbb{R}^d . It can be thought of as a random measure M on the Borel sets of \mathbb{R}^d that specifies the number of points $M(A)$ contained in A for each Borel set A . Given a point process M , the support of M is $[M] = \{x \in \mathbb{R}^d : M(\{x\}) = 1\}$, and points of $[M]$ are called M -points. We assume throughout that the law of our point process is isometry invariant. Another property we require is that it has finite intensity, meaning that the expected number of M -points in any fixed bounded Borel set B is finite. Also we assume that an index function can be assigned to the set of M -points almost always, meaning that there is an injective map from $[M]$ to the real numbers and that it is constructed in an equivariant, measurable way. (A mapping f from $[M]$ is equivariant with the point process if for any isometry γ of \mathbb{R}^d , $\gamma \circ f = f \circ \gamma$.) In what follows, we shall refer to this property by simply saying that M allows an *index function*. Having an index function is equivalent to saying that the group of isometries of $[M]$ is trivial almost always. For this equivalence, see [4]. Notice that the existence of an index function enables one to make a function (also called an index function) in an equivariant, measurable way that maps

¹ Research partially supported by NSF Grant DMS-0231224 and Hungarian National Foundation for Scientific Research Grants F026049 and T30074.

the pairs of $[M]$ to the reals injectively. For example, given a pair $\{x, y\}$, assume that the index of x is $\sum_{n \in \mathbb{Z}} a_n 10^n$, $a_i \in \{0, 1, \dots, 9\}$, and that of y is $\sum_{n \in \mathbb{Z}} b_n 10^n$. (Thus all but a finite number of the a_n and the b_n are 0 for $n \in \mathbb{Z}^+$.) Now let the index of $\{x, y\}$ be the greater of $\sum_n a_n 10^{2n} + \sum_k b_k 10^{2k+1}$ and $\sum_n b_n 10^{2n} + \sum_k a_k 10^{2k+1}$.

A general example of point processes where an index function exists are non-equidistant processes (meaning processes that with probability 1, the distance between any two points is different).

A *factor graph* or *factor* of M is a function that maps every point configuration $[M]$ to a graph defined on it (as vertex set) and such that this function is measurable and equivariant with the point process.

In [3], it is shown that in dimension at most 3, a *translation-equivariant* one-ended tree factor of the Poisson point process exists. Holroyd and Peres [4] give a construction that defines a 1-ended tree on the Poisson process in an *isometry-equivariant* way and for any dimension. However, their proof makes use of the independence, and in the same paper they ask whether a one-ended tree factor can be given for any ergodic point process that almost always has only the trivial symmetry. (They give an example where this assumption about the symmetries is not satisfied, namely, the point process got by shifting and rotating \mathbb{Z}^d in a uniform way. For this process, one cannot define the desired factor.) We give a positive answer to their question.

THEOREM 1.1. *Let M be a point process on \mathbb{R}^d that allows an index function. Then there exists a locally finite one-ended tree factor on M .*

As shown in [4], a one-ended tree factor gives rise to a two-ended path factor. Briefly, define an ordering on every set of siblings (using the ordering on $[M]$ given by the index function) and then order all the vertices similarly to the depth-first search in computer science.

It is also pointed out there, by a short mass-transport argument, that any one-ended tree that we could define in an equivariant way has to be locally finite.

The same paper asks what other classes of graphs can arise as a factor of the Poisson process. For example, for what n and d can \mathbb{Z}^n arise? This question, due to Steve Evans, will be answered in our fourth section. There, we prove the following.

THEOREM 1.2. *For any d and n , a point process M on \mathbb{R}^d that allows an index function has a \mathbb{Z}^n factor.*

2. A version of the Mass-Transport Principle

The following continuum form of the Mass Transport Principle (MTP) is from [2]. They state it for hyperbolic spaces, but, as mentioned there, it directly generalizes to Euclidean space.

Call a measure μ on $\mathbb{R}^d \times \mathbb{R}^d$ *diagonally invariant* if it satisfies

$$\mu(gA \times gB) = \mu(A \times B)$$

for all measurable $A, B \subset \mathbb{R}^d$ and $g \in \text{Isom}(\mathbb{R}^d)$.

LEMMA 2.1. *Let μ be a nonnegative, diagonally invariant Borel measure on $\mathbb{R}^d \times \mathbb{R}^d$. Suppose that $\mu(A \times \mathbb{R}^d) < \infty$ for some nonempty open $A \subset \mathbb{R}^d$. Then*

$$\mu(B \times \mathbb{R}^d) = \mu(\mathbb{R}^d \times B)$$

for all measurable $B \subset \mathbb{R}^d$. Moreover, there is a constant c such that $\mu(B \times \mathbb{R}^d) = c \text{Vol}(B)$.

COROLLARY 2.2. *Suppose that μ is a nonnegative, diagonally invariant Borel measure on $\mathbb{R}^d \times \mathbb{R}^d$ and that it is absolutely continuous with respect to Lebesgue measure. Let f_μ be its Radon-Nikodým derivative: $\mu(A \times A') = \int_A \int_{A'} f_\mu(x, y) dx dy$. Then $\int_{\mathbb{R}^d} f_\mu(x, y) dx = \int_{\mathbb{R}^d} f_\mu(y, x) dx = c$ for almost every y , with the constant c as in the previous lemma.*

The corollary follows from Lemma 2.1, because if the integrals are equal on every Borel set then the two functions are equal almost everywhere.

We will use the lemma and its corollary in the following way. For convenience, we state it as a separate lemma.

LEMMA 2.3. *Let $T(x, y, M)$ be a nonnegative, measurable “mass transport function”, defined for every configuration M and points x, y of \mathbb{R}^d . Suppose T is invariant under the isometries of the space, meaning $T(x, y, M) = T(\gamma x, \gamma y, \gamma M)$ for any $\gamma \in \text{Isom}(\mathbb{R}^d)$. Define $f(x, y) := \mathbf{E}T(x, y, M)$ and suppose that $\int_A \int_{\mathbb{R}^d} f(x, y) dx dy < \infty$ for some open $A \subset \mathbb{R}^d$. Then $\int_{\mathbb{R}^d} f(x, y) dx = \int_{\mathbb{R}^d} f(y, x) dx$ almost always.*

$T(x, y, M)$ is usually referred to as the amount of mass sent from x to y if the configuration is M . Then $\int_{\mathbb{R}^d} f(x, y) dx$ and $\int_{\mathbb{R}^d} f(y, x) dx$ can be thought of as the expected amount of mass sent into or sent out of y , respectively.

Proof. Let $\mu(A, A') := \mathbf{E} \int_A \int_{A'} T(x, y, M) dx dy$ and $f(x, y) := \mathbf{E}T(x, y, M)$. These are both isometry-invariant. Moreover, f is the Radon-Nikodým derivative of the extension of μ to $\mathcal{B}(\mathbb{R}^d \times \mathbb{R}^d)$, since

$$\int_A \int_{A'} f(x, y) dx dy = \int_A \int_{A'} \mathbf{E}T(x, y, M) dx dy = \mathbf{E} \int_A \int_{A'} T(x, y, M) dx dy = \mu(A, A')$$

by Fubini’s theorem for nonnegative functions. So if the assumption of the lemma about the existence of an open set A with $\mu(A \times \mathbb{R}^d) < \infty$ holds, then the lemma and the corollary apply. In particular, $f_\mu = f$ gives $\int_{\mathbb{R}^d} f(x, y) dx = \int_{\mathbb{R}^d} f(y, x) dx$ almost always. \square

3. Tree factor

In this section we prove Theorem 1.1. Actually, following [4], we define a *locally finite clumping*, which is a sequence of coarser and coarser partitions of $[M]$, defined on $[M]$ in an isometry-equivariant way, and so that in every partition, all the classes are finite. A class in one of the partitions is called a *clump*. A clumping is *connected* if any two vertices are in the same clump in one of the partitions (and hence all but in finitely many of them).

As shown in [4], a connected locally finite clumping gives rise to a locally finite tree with one end. To construct the tree, in the first partition connect every vertex to the vertex of the highest index in its clump. These edges define a forest in each clump of the second partition; for each tree in this forest, connect the vertex of highest index in the tree to the vertex of highest index in the whole clump (but do not connect that point to itself). With these new edges, we defined a tree in each clump of the second partition, which determine a forest in each clump of the third partition. Continue the process this way. The graph we get after infinitely many steps is clearly a forest, constructed in an isometry-equivariant way. It is also a tree, by connectedness of the clumping. It has only one end, because the only path starting from a vertex v to infinity is the one that goes through the vertices of greatest index in each clump which contains v .

We will need a few lemmas to construct the clumping. A subset of the vertex set of a graph G is called *independent*, if no two of its elements are adjacent.

LEMMA 3.1. *Let M be a point process and G be a locally finite graph on the vertex set $[M]$, defined in an isometry-equivariant way. There is a subset N of $[M]$ that is an independent set of G and is defined in an equivariant, measurable way.*

Proof. Let ι be the index function on points of the process, and for a $q \in \mathbb{Q}$ denote by $N(q)$ the set of points v such that $|\iota(v) - q| < |\iota(w) - q|$ for all G -neighbors w of v . Note that $N(q)$ is always an independent set (possibly empty). Since the union over all rational q of $N(q)$ is all points of the process (with probability one), there exist rational numbers q such that $\mathbf{P}(N(q) \text{ nonempty}) > 0$. Call such q good. Enumerate the rationals, and let $q([M])$ be the first good rational for the configuration $[M]$. Define $N = N(q([M]))$. \square

The present proof of this lemma comes from Yuval Peres, replacing the original, longer one that used a result from [1].

COROLLARY 3.2. *For all k , there is a nonempty subset V_k of $[M]$ chosen in an equivariant way such that the distance between any two vertices in V_k is at least 2^k .*

Proof. Connect two points of $[M]$ if their distance is less than 2^k and apply the lemma. \square

Finally, we shall use the following simple geometric fact.

LEMMA 3.3. *Let $K \subset \mathbb{R}^d$ be a convex polyhedron that contains a ball of radius r . Then the volume of K divided by the surface area of K is at least cr , where $c > 0$ is a constant depending only on d .*

Proof. Connect the center P of the ball to each vertex, thus subdividing the polygon to “pyramids”, whose apices are P . The altitudes of the pyramids from P are at least r by the hypothesis, and this gives the claim. (The area of the bases sum up to the surface area, the volumes of the pyramids to the volume of K .) \square

By Corollary 3.2, there is a sequence V_k of subsets of $[M]$, constructed in an equivariant way, such that the minimal distance between any two points of V_k is at least 2^k . Let B_k be the union of the boundaries of the Voronoi cells on V_k . We show that the Voronoi cell containing some fixed point x in \mathbb{R}^d is almost always finite.

Otherwise, define a mass-transport function $T(x, y, M)$ to be 1 if x and y are in the same Voronoi cell (say, the one corresponding to an M -point P) and if y is in the ball of volume 1 around P . Let $T(x, y, M)$ be 0 otherwise. Define $f(x, y)$ as $\mathbf{E}T(x, y, M)$. So $\int_{\mathbb{R}^d} f(x, y) dy \leq 1$. This implies also that the assumption of Lemma 2.3 holds. However, if the Voronoi cell containing x is infinite with positive probability, then $\int f(y, x) dy = \infty$. This contradicts the lemma. Thus we proved:

REMARK 3.4. The Voronoi cells of any invariant point process are almost always bounded.

After a preparatory, intuitively clear lemma, we shall define the connected, locally finite clumping on $[M]$. Denote by \mathcal{B} the set of measurable sets of \mathbb{R}^d .

LEMMA 3.5. *Let O be a fixed point of \mathbb{R}^d . Suppose there is an equivariant measurable partition $\mathcal{P}([M]) = \mathcal{P}$ of \mathbb{R}^d such that all the parts are bounded with probability 1, and suppose that for each part P in \mathcal{P} a measurable subset of it is given by a measurable mapping $\phi = \phi(\mathcal{P}, P)$. Suppose that $(\mathcal{P}, \phi(\mathcal{P}, \cdot))$ is invariant under isometries of \mathbb{R}^d .*

Assume further, that for each $P \in \mathcal{P}([M])$, $\text{Vol}(\phi(\mathcal{P}, P))/\text{Vol}(P) \leq p$. Then the probability that O lies in $\cup_{P \in \mathcal{P}} \phi(\mathcal{P}, P)$ is at most p .

Proof. Define $T(x, y, M)$ to be $1/\text{Vol}(P) (> 0)$ if y is in $P \in \mathcal{P}$ and x is in $\phi(\mathcal{P}, P)$. Let $T(x, y, M)$ be 0 otherwise. Denote, as usual, $f(x, y) := \mathbf{E}T(x, y, M)$. Now the expected mass

sent out from O is $\int_{\mathbb{R}^d} f(O, y) dy = \mathbf{P}[O \in \cup_{P \in \mathcal{P}} \phi(\mathcal{P}, P)]$. The expected mass coming into O is $\int_{\mathbb{R}^d} f(y, O) dy \leq \sup \text{Vol}(\phi(\mathcal{P}, P)) / \text{Vol}(P) \leq p$. Here the supremum is the essential supremum over configurations of \mathcal{P} of the supremum over $P \in \mathcal{P}$.

So by Lemma 2.3, $\mathbf{P}[O \in \cup_{P \in \mathcal{P}} \phi(\mathcal{P}, P)] \leq p$. \square

Define a partition \mathcal{P}_k of $[M]$ by saying that $x, y \in [M]$ are in the same clump of \mathcal{P}_k iff they are in the same component of $\mathbb{R}^d \setminus \cup_{i=k}^{\infty} B_i$. This clumping is locally finite with probability 1 by finite intensity and the fact that the cells defining \mathcal{P}_i are bounded almost always.

PROPOSITION 3.6. *The \mathcal{P}_k define a connected, locally finite clumping on $[M]$.*

Proof. What we have to prove is that the clumping is connected. This is equivalent to saying that for any fixed ball Q in \mathbb{R}^d , Q is intersected by only a finite number of the B_k 's almost always, and so any two M -points inside Q are in the same clump of \mathcal{P}_k if k is large enough.

Denote by δ the diameter of Q . Now let N_k be the set of points in \mathbb{R}^d of distance less than δ from B_k , the union of the *thickened boundaries* of the Voronoi cells of V_k . Notice that the volume of the thickened boundary of a cell is bounded from above by a times the surface area of the cell, where a is a constant depending only on δ . Here we are using that every cell contains a ball of radius 2^k , by the choice of V_k .

Hence by Lemma 3.3, for any Voronoi cell on V_k , the volume of the cell is at least $c 2^k$ times as much as the volume of the thickened boundary of that cell, with some constant c independent of k .

Q is intersected by B_k only if N_k contains the center O of Q . So it suffices to prove that for any fixed point O , the expected number of N_k 's that contain O is finite.

In Lemma 3.5 put \mathcal{P} to be the Voronoi cells on V_k (k fixed), and $\phi(P)$ to be the intersection of the Voronoi cell P with the thickened boundary. The lemma combined with Remark 3.4 says that the probability that O is contained in N_k is at most $2^{-k}/c$. Hence the expected number of N_k 's containing O is at most $1/c$, and we are done. \square

4. Grid factor

Once we have the 1-ended, locally finite tree factor, we can use it to construct a connected clumping with special properties.

THEOREM 4.1. *There is a connected clumping $\{\mathcal{P}_i\}$ such that the clumps in \mathcal{P}_i have size 2^i for each $i \geq 0$.*

Proof. Take a 1-ended tree factor, which exists by Theorem 1.1, and denote by T the actual tree given by it on the configuration $[M]$. Everything we do will be obviously equivariant (given that the tree was constructed in an equivariant way). When we have to decide, say, how to make pairs of the points of a given finite set (and which one to leave without a pair if there is an odd number of them), we can always use the index function to do this deterministically and equivariantly. We can say, for example, that we match the two with the highest indices, then the next two, etc.

Define the partition \mathcal{P}_0 to consist of singletons.

Now we define \mathcal{P}_1 in countably many steps, each step having two phases. To begin with, define two-element clumps by first forming as many pairs as possible in each set of leaves of $T_0 := T$ with a common parent. Put these pairs in \mathcal{P}_1 (so that they will be clumps of it) and delete them from T_0 . We are left with a subtree T'_0 of T_0 such that from each set of sibling leaves

of T_0 , at most one is still in T'_0 . Now, in the second phase, form all the pairs $\{x, y\}$ such that x was a leaf in T_0 and y is its parent.

Put these new pairs as clumps in \mathcal{P}_1 , and delete them from T'_0 to get T_1 . Observe that T_1 is a tree by our definitions.

In the next step, do the same two phases for T_1 as we did for T_0 . Call the tree remaining at the end T_2 , and so on. After countably many steps, all the vertices of T are in some clump of \mathcal{P}_1 since the number of descendants of each vertex strictly decreases in each step (each T_i) until the vertex is removed from the actual tree.

To define \mathcal{P}_2 , identify the vertices in every pair of \mathcal{P}_1 . So we identify either connected vertices or siblings. The first case results in a loop; delete it. The second case results in a pair of parallel edges; delete one of the copies. The resulting graph is a 1-ended tree \hat{T} , and each vertex of it represents a clump of \mathcal{P}_1 . So the pairs on \hat{T} defined in the same way as we did in the previous two paragraphs for T will determine the \mathcal{P}_2 as we desire.

We proceed similarly to get the \mathcal{P}_i (using \mathcal{P}_{i-1}).

Now, it is easy to see that the clumping defined is connected. That is, any $x, y \in V(T)$ ($= [M]$) are in the same clump of \mathcal{P}_k if k is large enough. Indeed, we may assume that x is a descendant of y (otherwise choose a common ancestor z and the bigger of the clumps containing $\{x, z\}$ and $\{y, z\}$ respectively). When we defined \mathcal{P}_i we used a tree, denote it by Υ_i , that came from the tree Υ_{i-1} of \mathcal{P}_{i-1} by identifying the pairs of a complete pairing of the vertices. (Υ_1 was T itself.) Thus every vertex in Υ_i is the result of a sequence of fusions and hence corresponds to 2^{i-1} vertices of T . Denote by v_i the vertex of Υ_i that v was fused into after the sequence of i identifications. Notice that if v_i has at least one descendant, then it has strictly fewer descendants than v_{i-1} . So for i large enough, v_i has no descendants. For these i , all the descendants of v in T are in the same clump of \mathcal{P}_i . \square

Now we are ready to prove Theorem 1.2.

Proof of Theorem 1.2.

Define a subgrid K_k of \mathbb{Z}^n to be the subgraph induced by the vertex set

$$V(K_k) = \{1, \dots, 2^j\}^{n-i} \times \{1, \dots, 2^{j+1}\}^i,$$

where $k = jn + i$, $i \in \{0, \dots, n-1\}$. Notice that K_{k+1} arises as two copies of K_k glued together along a “hyperface”.

Now let \mathcal{P}_i be a clumping as in Theorem 4.1. Use the index function to define a graph isomorphic to K_i on each clump C of \mathcal{P}_i recursively. For the two-element clumps of \mathcal{P}_1 define K_1 by making the two vertices adjacent. Given two clumps C_1 and C_2 of \mathcal{P}_i whose union is the clump C of \mathcal{P}_{i+1} , define a K_{i+1} on C by adding new edges to the union of the two K_{i-1} -graphs (defined on C_1 and C_2). If there are more ways to do it, the index function can be used to make it deterministic.

The limiting graph G is connected and clearly is a subgraph of \mathbb{Z}^n , because any finite neighbourhood of any point in it is isomorphic to a subgraph of some K_i , thus defining an embedding of G in \mathbb{Z}^n . Moreover, it is such that if ϕ is an embedding of G to \mathbb{Z}^n , then for any axis of \mathbb{Z}^n there is at least one direction such that for any vertex v in $\phi(G)$ the infinite path “parallel” to the axis and starting from v in this direction is in $\phi(G)$. This implies that there is essentially one embedding of G to \mathbb{Z}^n , meaning that any embedding arises from another by composing it with an isometry of \mathbb{Z}^n . (This is a consequence of the fact that for any two subgraphs of \mathbb{Z}^n that are both isomorphic to the graph induced by $\{(x_1, \dots, x_n) \in \mathbb{Z}^n, x_i \geq 0\}$ in \mathbb{Z}^n , there is an isomorphism between them that extends to an automorphism of \mathbb{Z}^n . This claim

is intuitively obvious and one can give a proof without any difficulty.) So it is well defined to speak about paths in G that are parallel to an axis - just take any embedding in \mathbb{Z}^n .

Suppose now that G is not equal to \mathbb{Z}^n . Then for every vertex v and axis x_i of \mathbb{Z}^n such that there is only one edge in G incident to v and parallel to the axis x_i , let v send mass 1 to every point on the singly infinite path starting from v and parallel to x_i . The expected mass received is at most $2n$, while the expected mass sent out is infinite if the limit graph has “boundary points” (points of degree less than $2n$) with positive probability. This contradiction with Lemma 2.1 finishes the proof. \square

Let us mention that the clumping provided by Theorem 4.1 gives rise to easy constructions of other factors, such as 1-ended locally finite trees of arbitrary growth rate. For this, take the clumping with clumps of size 2^n , where n goes through a sequence $\{n_k\}_{k=1}^{\infty}$ of real numbers that go to infinity as fast as we wish. Then the construction used to get a one-ended tree from a clumping will give us the tree that grows “fast”.

Finally we indicate that the statements of Theorem 1.1 and Theorem 1.2 hold also in the following modified setting. Let G be any group of isometries of R^d , and modify the definition of equivariance to refer to all isometries in G . Then the conclusions of the theorems hold (with the same proofs) for any G -invariant process with a G -equivariant index function.
