# KRYLOV SUBSPACE SPECTRAL METHODS FOR VARIABLE-COEFFICIENT INITIAL-BOUNDARY VALUE PROBLEMS* 

JAMES V. LAMBERS ${ }^{\dagger}$

#### Abstract

This paper presents an alternative approach to the solution of diffusion problems in the variablecoefficient case that leads to a new numerical method, called a Krylov subspace spectral method. The basic idea behind the method is to use Gaussian quadrature in the spectral domain to compute components of the solution, rather than in the spatial domain as in traditional spectral methods. For each component, a different approximation of the solution operator by a restriction to a low-dimensional Krylov subspace is employed, and each approximation is optimal in some sense for computing the corresponding component. This strategy allows accurate resolution of all desired frequency components without having to resort to smoothing techniques to ensure stability.

1. Introduction. Let $L$ be a self-adjoint second-order differential operator of the form

$$
\begin{equation*}
L u=-\left(p u_{x}\right)_{x}+q u \tag{1.1}
\end{equation*}
$$

where $p(x)>0$ and $q(x) \geq 0$ are $2 \pi$-periodic functions. We consider the diffusion equation on a bounded domain,

$$
\begin{gather*}
u_{t}+L u=0, \quad 0<x<2 \pi, \quad t>0  \tag{1.2}\\
u(x, 0)=f(x), \quad 0<x<2 \pi \tag{1.3}
\end{gather*}
$$

with periodic boundary conditions

$$
\begin{equation*}
u(0, t)=u(2 \pi, t), \quad t>0 \tag{1.4}
\end{equation*}
$$

In Section 4 we will discuss applications of the methods presented in this paper to more general problems.
1.1. Difficulties of Variable-Coefficient Problems. Spectral methods are extremely effective for solving the problem (1.2), (1.3), (1.4) in the case where the coefficients $p$ and $q$ are constant; see for instance [1], [7]. Unfortunately, the variable-coefficient case presents some difficulties for these methods:

- Let $\left\{\phi_{\omega}(x)\right\}_{\omega=0}^{N-1}$ be the natural basis of $N$ trial functions defined by

$$
\phi_{\omega}(x)=\frac{1}{\sqrt{2 \pi}} e^{i \omega x} .
$$

In the constant-coefficient case, these trial functions are eigenfunctions of $L$, but this is not true in the variable-coefficient case; in fact, the matrix of $L$ in this basis is a full matrix in the general case.

- The phenomenon of aliasing can lead to weak instability (see for instance [5]), which manifests itself in the sudden blow-up of the solution. Unlike strong instability, it cannot be overcome simply by using a smaller time step, but rather one must use more grid points or filtering techniques (see [1]).

[^0]As a result, substantially more computational effort must be expended for less information than in the constant-coefficient case. As variable-coefficient problems can be viewed as perturbations of their constant-coefficient counterparts, it should be possible to develop numerical methods that exploit this useful perspective.
1.2. Proposed Approach. Traditional Galerkin methods seek a solution in the space of trial functions that satisfies the PDE (1.2) in an average sense. In this paper we will instead compute an approximate solution $\tilde{u}(x, t)$ of the form

$$
\tilde{u}(x, t)=\sum_{\omega=1}^{N} \hat{u}_{\omega}(t) \phi_{\omega}(x)
$$

where $\left\{\phi_{\omega}\right\}_{\omega=1}^{N}$ is an orthonormal set of trial functions. For each $t>0$, the coefficients $\left\{\hat{u}_{\omega}(t)\right\}_{\omega=1}^{N}$ are approximations of the coefficients of the exact solution $u(x, t)=e^{-L t} f(x)$ in the basis $\left\{\phi_{\omega}\right\}$. Specifically,

$$
\hat{u}_{\omega}(t)=\left\langle\phi_{\omega}, \tilde{u}(\cdot, t)\right\rangle \approx\left\langle\phi_{\omega}, \exp [-L t] f\right\rangle
$$

where the inner product $\langle\cdot, \cdot\rangle$ is defined by

$$
\langle f, g\rangle=\int_{0}^{2 \pi} \overline{f(x)} g(x) d x
$$

and the solution operator $\exp [-L t]$ is approximated using Krylov subspaces of $L$. This approach, in and of itself, is not new; for example, Hochbruck and Lubich have developed a method for approximating $\exp [-A t] \mathbf{v}$, for a given vector $\mathbf{v}$ and Hermitian positive definite matrix $A$, using a Krylov subspace

$$
\begin{equation*}
\mathcal{K}(A, \mathbf{v}, m)=\operatorname{span}\left\{\mathbf{v}, A \mathbf{v}, A^{2} \mathbf{v}, \ldots, A^{m-1} \mathbf{v}\right\} \tag{1.5}
\end{equation*}
$$

for some choice of $m$. However, this approach is most accurate when the eigenvalues of $A$ are clustered, which is not the case for a matrix that represents a discretization of $L$. For such stiff systems, one must take care to choose $m$ sufficiently large, or $t$ sufficiently small, in order to obtain sufficient accuracy (see [8] for details).

Our approach is to use a different approximation for each component $\hat{u}_{\omega}(t)$. By writing

$$
\left\langle\phi_{\omega}, e^{-L t} f\right\rangle=\frac{1}{4 \delta}\left[\left\langle\phi_{\omega}+\delta f, e^{-L t}\left(\phi_{\omega}+\delta f\right)\right\rangle-\left\langle\phi_{\omega}-\delta f, e^{-L t}\left(\phi_{\omega}-\delta f\right)\right\rangle\right]
$$

for some nonzero constant $\delta$, we can reduce the problem of approximating $\left\langle\phi_{\omega}, e^{-L t} f\right\rangle$ to that of approximating quadratic forms

$$
\left\langle v_{\omega}, e^{-L t} v_{\omega}\right\rangle
$$

where $v_{\omega}=\phi_{\omega} \pm \delta f$. Each such quadratic form is computed using the Krylov subspace $\mathcal{K}\left(L, v_{\omega}, n\right)$ for some $n$. In this way, each frequency component of $\tilde{u}(x, t)$ can be computed independently, using an approximation that is, in some sense, optimal for that component; we will elaborate on this statement in Section 3. Furthermore, as we will see in Section 2, high-order temporal accuracy can be obtained using only low-dimensional Krylov subspaces.
2. Krylov Subspace Spectral Methods. In this section we describe Krylov subspace spectral methods and prove results concerning their convergence.
2.1. Elements of Functions of Matrices. We first discuss the approximation of quadratic forms

$$
\langle u, f(L) u\rangle
$$

where, in our application, $f(\lambda)=\exp [-\lambda t]$ for some $t>0$. We first discretize the operator $L$ on a uniform grid

$$
\begin{equation*}
x_{j}=j h, \quad j=0,1, \ldots, N-1, \quad h=\frac{2 \pi}{N} \tag{2.1}
\end{equation*}
$$

where $N$ is the number of gridpoints. On this grid, $L$ is represented by an $N \times N$ symmetric positive definite matrix $L_{N}$ defined by

$$
\begin{equation*}
S_{N}(t)=\exp \left[-L_{N} t\right], \quad\left[L_{N}\right]_{j k}=-p(j h)\left[D_{N}^{2}\right]_{j k}-p^{\prime}(j h)\left[D_{N}\right]_{j k}+q(j h) \tag{2.2}
\end{equation*}
$$

where $D_{N}$ is a discrete differentiation operator defined on the space of grid functions. The function $u$ is represented by an $N$-vector

$$
\mathbf{u}_{N}=\left[\begin{array}{lll}
u\left(x_{0}\right) & \cdots & u\left(x_{N-1}\right)
\end{array}\right]^{T}
$$

We denote the eigenvalues of $L_{N}$ by

$$
b=\lambda_{1} \geq \lambda_{2} \geq \cdots \geq \lambda_{N}=a>0
$$

and the corresponding eigenvectors by $\mathbf{q}_{1}, \ldots, \mathbf{q}_{N}$. We can compute the quantity

$$
\begin{equation*}
\mathbf{u}_{N}^{T} f\left(L_{N}\right) \mathbf{u}_{N} \tag{2.3}
\end{equation*}
$$

using a Gaussian quadrature rule to evaluate the Riemann-Stieltjes integral

$$
\begin{equation*}
I[f]=\int_{a}^{b} f(\lambda) d \alpha(\lambda) \tag{2.4}
\end{equation*}
$$

where the measure $\alpha(\lambda)$ is defined by

$$
\alpha(\lambda)= \begin{cases}0 & \lambda<a  \tag{2.5}\\ \sum_{j=i+1}^{N}\left|\mathbf{u}_{N}^{T} \mathbf{q}_{j}\right|^{2} & \lambda_{i+1} \leq \lambda<\lambda_{i} \\ \sum_{j=1}^{N}\left|\mathbf{u}_{N}^{T} \mathbf{q}_{j}\right|^{2} & b \leq \lambda\end{cases}
$$

The nodes and weights of the Gaussian quadrature rule can be obtained by applying the symmetric Lanczos algorithm (see [3]) to $L_{N}$ with initial vector $\mathbf{u}_{N}$. After $K$ iterations, we obtain a $K \times K$ tridiagonal matrix

$$
J_{K}=\left[\begin{array}{ccccc}
\alpha_{1} & \beta_{1} & & &  \tag{2.6}\\
\beta_{1} & \alpha_{2} & \beta_{2} & & \\
& \ddots & \ddots & \ddots & \\
& & \ddots & \ddots & \beta_{K-1} \\
& & & \beta_{K-1} & \alpha_{K}
\end{array}\right]
$$

whose eigenvalues are the Gaussian quadrature rules for the integral (2.4). The weights are the squares of the first components of the eigenvectors of $J_{K}$. With $f(\lambda)=e^{-\lambda t}$, Gaussian quadrature yields a lower bound for $I[f]$ (see [15] for details). We can extend $J_{K}$ to obtain a tridiagonal matrix $J_{K+1}$ that has an eigenvalue at $a$. The resulting rule is a Gauss-Radau rule, which yields an upper bound for $I[f]$ (see [3]).
2.2. Algorithm Description. We now describe an algorithm for solving (1.2), (1.3), (1.4) using the quadrature rules described above. First, we consider the computation of quadratic forms of the form (2.3), where $f(\lambda)=\exp [-\lambda t]$ for given $t$.

For convenience, We denote by $V_{N}$ the space of real-valued $2 \pi$-periodic functions of the form

$$
f(x)=\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2} e^{i \omega x} \hat{f}(\omega), \quad 0<x<2 \pi
$$

and assume that the initial data $f(x)$ and the coefficients $p$ and $q$ of the operator $L$ belong to $V_{N}$. Furthermore, we associate a grid function $\mathbf{u}_{N}$ with the function $u_{N}(x) \in V_{N}$ defined by

$$
u_{N}(x)=\sum_{\omega=-N / 2+1}^{N / 2-1} \tilde{u}_{N}(\omega) e^{i \omega x}
$$

where

$$
\tilde{u}_{N}(\omega)=\frac{h_{N}}{\sqrt{2 \pi}} \sum_{j=0}^{N-1} e^{-i \omega j h_{N}}\left[\mathbf{u}_{N}\right]_{j}, \quad h_{N}=\frac{2 \pi}{N}
$$

If we discretize the operator $L$ by an $N \times N$ matrix $L_{N}$ and compute $\mathbf{v}_{N}=L_{N} \mathbf{u}_{N}$, then high-frequency components of $v_{N}$ are lost due to aliasing.

We can avoid this loss of information using a finer grid. Given a grid function $\mathbf{f}$ defined on an $N$-point uniform grid of the form (2.1), the grid function $\mathbf{f}_{M}$, for $M>N$, is defined by interpolating the values of $\mathbf{f}$ on the finer $M$-point grid; i.e.,

$$
\left[\mathbf{f}_{M}\right]_{j}=\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2-1} e^{i \omega 2 \pi j / M} \tilde{f}(\omega), \quad j=0, \ldots, M-1
$$

where

$$
\tilde{f}(\omega)=\left[\frac{h_{N}}{\sqrt{2 \pi}} \sum_{k=0}^{N-1} e^{-i \omega k h_{N}}[\mathbf{f}]_{k}\right]
$$

If $M \geq 2 N$, and the coefficients of $L$ belong to $V_{N}$, then $\mathbf{v}_{M}=L_{M} \mathbf{u}_{M}$ retains the highfrequency components of $L u_{N}$.

In the following algorithm, we compute bounds on $\left\langle u_{N}, e^{-L t} u_{N}\right\rangle$ using a $K$-point Gaussian rule and a $(K+1)$-point Gauss-Radau rule. Both quadrature rules are obtained by applying the symmetric Lanczos algorithm to the matrix $L_{M_{K}}$ with initial vector $\mathbf{u}_{M_{K}}$, where $M_{K}=2^{K} N$. Because the coefficients of $L$ belong to $V_{N}$, we do not need to work with $L_{M_{K}}$ explicitly at each iteration; we can instead begin with a $2 N$-point grid and refine after each iteration.

After $K$ iterations of the Lanczos algorithm, the $K \times K$ tridiagonal matrix $J_{K}$ defined in (2.6) is obtained. The Gaussian quadrature approximation of $\left\langle u_{N}, e^{-L t} u_{N}\right\rangle$ is given by $\mathbf{u}_{N}^{T} \mathbf{u}_{N}\left[\exp \left(-J_{K} t\right)\right]_{11}$. Then, $J_{K}$ is extended to a matrix $J_{K+1}$ that has an eigenvalue that approximates the smallest eigenvalue of $L$. For details on the extension of $J_{K}$, see [3]. Finally, the Gauss-Radau approximation of $\left\langle u_{N}, e^{-L t} u_{N}\right\rangle$ is given by $\mathbf{u}_{N}^{T} \mathbf{u}_{N}\left[\exp \left(-J_{K+1} t\right)\right]_{11}$.

We now describe the algorithm in full detail.

Algorithm 2.1 Given a real-valued grid function $\mathbf{u}_{N}$ defined on an $N$-point uniform grid (2.1), a self-adjoint differential operator $L$ of the form (1.1) and a scalar $t$, the following algorithm computes bounds $z_{1}$ and $z_{2}$ on $\mathbf{u}_{M_{K}}^{T} \exp \left[-L_{M_{K}} t\right] \mathbf{u}_{M_{K}}$, where $K$ is the number of Gaussian quadrature nodes to be computed and $M_{K}=2^{K} N$.

```
\(\beta_{0}=\left\|\mathbf{u}_{N}\right\|_{2}\)
\(\mathbf{f}_{N}^{1}=\mathbf{u}_{N} / \beta_{0}\)
\(\mathbf{f}_{N}^{0}=\mathbf{0}\)
\(M=2 N\)
for \(j=1, \ldots, K\)
    \(\mathbf{h}_{M}^{j}=L_{M} \mathbf{f}_{M}^{j}\)
    \(\alpha_{j}=\left[\mathbf{f}_{M}^{j}\right]^{T} \mathbf{h}_{M}^{j}\)
    \(\mathbf{r}_{M}^{j}=\mathbf{h}_{M}^{j}-\alpha_{j} \mathbf{f}_{M}^{j}-\gamma_{j-1} \mathbf{f}_{M}^{j-1}\)
    \(\beta_{j}=\left\|\mathbf{r}_{M}^{j}\right\|_{2}\)
    \(\mathbf{f}_{M}^{j+1}=\mathbf{r}_{M}^{j} / \beta_{j}\)
    \(M=2 M\)
end
Let \(J_{K}\) be the \(K \times K\) matrix defined by (2.6)
\(z_{1}=h \beta_{0}^{2}\left[\exp \left(-J_{K} t\right)\right]_{11}\)
```

Let $a$ be an approximation to the smallest eigenvalue of $L$
Solve $\left(J_{K}-a I\right) \delta=\beta_{K}^{2} \mathbf{e}_{K}$
$\alpha_{K+1}=a+\delta_{K}$
Let $J_{K+1}$ be the matrix obtained from $J_{K}$ by adding
$\alpha_{K+1}$ to the diagonal, $\beta_{K}$ to the superdiagonal
and $\beta_{K}$ to the subdiagonal
$z_{2}=h \beta_{0}^{2}\left[\exp \left(-J_{K+1} t\right)\right]_{11}$
The approximation to the smallest eigenvalue of $L$, required by the Gauss-Radau rule, can be obtained by applying the symmetric Lanczos algorithm to a discretization of $L$ with initial vector $\left[\begin{array}{cccc}1 & 1 & \cdots & 1\end{array}\right]^{T}$. This choice of initial vector is motivated by the fact that, as $|\omega|$ increases, $L e^{i \omega x} \sim p(x)|\omega|^{2} e^{i \omega x}$. Therefore, in order to obtain a function $u$ for which $\|L u\| /\|u\|$ is as small as possible, it is a good heuristic to avoid high frequencies.

Now, we can describe an algorithm for computing the approximate solution $\tilde{u}(x, t)$ of (1.2), (1.3), (1.4) at times $\Delta t, 2 \Delta t, \ldots, n \Delta t=t_{\text {final }}$. At each time step, we compute approximate Fourier components of the solution by using the polar decomposition

$$
\begin{equation*}
\mathbf{u}^{T} f(A) \mathbf{v}=\frac{1}{4}\left[(\mathbf{u}+\mathbf{v})^{T} f(A)(\mathbf{u}+\mathbf{v})-(\mathbf{u}-\mathbf{v})^{T} f(A)(\mathbf{u}-\mathbf{v})\right] \tag{2.7}
\end{equation*}
$$

to express the Fourier components in terms of quadratic forms, which in turn are approximated using Algorithm 2.1.

To avoid complex arithmetic, we use the grid functions

$$
\begin{aligned}
& {\left[\hat{\mathbf{c}}_{\omega}\right]_{j}=\frac{1}{\sqrt{\pi}} \cos (\omega j h), \quad j=0, \ldots, N-1, \quad \omega=1, \ldots, N / 2-1} \\
& {\left[\hat{\mathbf{s}}_{\omega}\right]_{j}=\frac{1}{\sqrt{\pi}} \sin (\omega j h), \quad j=0, \ldots, N-1, \quad \omega=1, \ldots, N / 2-1}
\end{aligned}
$$

and

$$
\left[\hat{\mathbf{e}}_{0}\right]_{j}=\frac{1}{\sqrt{2 \pi}}, \quad j=0, \ldots, N-1
$$

Also, it will be assumed that all bounds on quantities of the form $\mathbf{u}^{T} \exp (-A \Delta t) \mathbf{u}$, for any matrix $A$ and vector $\mathbf{u}$, are computed using Algorithm 2.1.

```
Algorithm 2.2 Given a grid function \(\mathbf{f}_{N}\) representing the initial data \(f(x)\) on a uniform \(N\) -
point grid of the form (2.1), a final time \(t_{\text {final }}\) and a timestep \(\Delta t\) such that \(t_{\text {final }}=n \Delta t\)
for some integer \(n\), the following algorithm computes an approximation \(\tilde{\mathbf{u}}_{j}^{n+1}\) to the solution
\(u(x, t)\) of (1.2), (1.3), (1.4) evaluated at each gridpoint \(x_{j}=j h\) for \(j=0,1, \ldots, N-1\) with
\(h=2 \pi / N\) and times \(t_{n}=n \Delta t\) for \(n=0,1, \ldots, t_{\text {final }} / \Delta t\).
\(\tilde{\mathbf{u}}^{0}=\mathbf{f}_{N}\)
for \(n=0,1, \ldots, t_{\text {final }} / \Delta t\) do
    Choose a nonzero constant \(\delta\)
    \(\mathbf{v}=\hat{\mathbf{e}}_{0}-\delta \tilde{\mathbf{u}}^{n}\)
    \(\mathbf{w}=\hat{\mathbf{e}}_{0}+\delta \tilde{\mathbf{u}}^{n}\)
    Compute bounds \(e_{11}\) and \(e_{12}\) for \(\mathbf{v}_{M_{K}}^{T} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{v}_{M_{K}}\)
    Compute bounds \(e_{21}\) and \(e_{22}\) for \(\mathbf{w}_{M_{K}}^{T} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{w}_{M_{K}}\)
    Let \(\hat{\mathbf{u}}_{0}^{n+1}=\left(e_{2 i}-e_{1 j}\right) /(4 \delta)\) where \(i\) and \(j\)
        are chosen to minimize error in \(\hat{\mathbf{u}}_{0}^{n+1}\)
    for \(\omega=1, \ldots, N / 2-1\)
        \(\mathbf{v}=\hat{\mathbf{c}}_{\omega}-\delta \tilde{\mathbf{u}}^{n}\)
        \(\mathbf{w}=\hat{\mathbf{c}}_{\omega}+\delta \tilde{\mathbf{u}}^{n}\)
        Compute bounds \(c_{11}\) and \(c_{12}\) for \(\mathbf{v}_{M_{K}}^{T} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{v}_{M_{K}}\)
        Compute bounds \(c_{21}\) and \(c_{22}\) for \(\mathbf{w}_{M_{K}}^{T} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{w}_{M_{K}}\)
        \(\mathbf{v}=\hat{\mathbf{s}}_{\omega}-\delta \tilde{\mathbf{u}}^{n}\)
        \(\mathbf{w}=\hat{\mathbf{s}}_{\omega}+\delta \tilde{\mathbf{u}}^{n}\)
        Compute bounds \(s_{11}\) and \(s_{12}\) for \(\mathbf{v}_{M_{K}}^{T} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{v}_{M_{K}}\)
        Compute bounds \(s_{21}\) and \(s_{22}\) for \(\mathbf{w}_{M_{K}}^{T_{K}} \exp \left[-L_{M_{K}} \Delta t\right] \mathbf{w}_{M_{K}}\)
        Let \(c_{\omega}=\left(c_{2 i}-c_{1 j}\right) /(4 \delta)\) where \(i\) and \(j\)
            are chosen to minimize error in \(c_{\omega}\)
        Let \(s_{\omega}=\left(s_{2 i}-s_{1 j}\right) /(4 \delta)\) where \(i\) and \(j\)
            are chosen to minimize error in \(s_{\omega}\)
        \(\hat{\mathbf{u}}_{\omega}^{n+1}=c_{\omega}+i s_{\omega}\)
        \(\hat{\mathbf{u}}_{-\omega}^{n+1}=c_{\omega}-i s_{\omega}\)
    end
    \(\tilde{\mathbf{u}}^{n+1}=T^{-1} \hat{\mathbf{u}}^{n+1}\) (inverse discrete Fourier transform)
end
```

In computing quantities of the form $\mathbf{u}^{T} f(A) \mathbf{v}$ using the polar decomposition (2.7), this algorithm actually computes $\frac{1}{\delta}\left[\mathbf{u}^{T} f(A)(\delta \mathbf{v})\right]$ where the scalar $\delta$ is chosen at the beginning of each time step. On the one hand, smaller values of $\delta$ are desirable because the quadrature error is reduced when the vector $\mathbf{w}$ in $\mathbf{w}^{T} f(A) \mathbf{w}$ is an approximate eigenvector of the matrix $A$. However, $\delta$ should not be chosen to be so small that $\mathbf{u}$ and $\mathbf{u} \pm \delta \mathbf{v}$ are virtually indistinguishable for the given precision. In practice, it is wise to choose $\delta$ to be proportional to $\left\|\tilde{\mathbf{u}}_{n}\right\|$ when computing $\tilde{\mathbf{u}}_{n+1}$. This explains why $\delta$ is chosen at the beginning of each time step in the preceding algorithm.

Various strategies can be used to determine whether the upper or lower bound on each integral should be used in computing the approximation to each component of the solution. For example, a Gauss-Radau rule with an appropriate choice of prescribed node can be compared with the approximation computed using a Gaussian rule in order to estimate its accuracy. Alternatively, Gauss-Kronrod rules can be used from the previously constructed Gaussian rules to estimate the accuracy of each bound; for details see [2].
2.3. Convergence Analysis. We now prove that Algorithm 2.2 is convergent. The approach is analogous to that used to prove convergence for finite-difference schemes. We will denote by $\tilde{S}(\Delta t, \Delta x ; f)$ the result of applying Algorithm 2.2 to the function $f(x)$ using a discretization of space and time with uniform spacings $\Delta x$ and $\Delta t$, respectively.
2.3.1. Consistency. First, we will prove that the approximate Fourier components of the solution at time $\Delta t$ computed by Algorithm 2.2, using a $K$-point Gaussian quadrature rule, converge to the corresponding Fourier components of the exact solution as $\Delta t \rightarrow 0$ at a rate of $O\left(\Delta t^{2 K}\right)$. In order to analyze the quadrature error for the integrand $f(\lambda)=\exp [-\lambda t]$, we first need to consider the case $f(\lambda)=\lambda^{j}$.

Lemma 2.1. Let $A$ be an $n \times n$ symmetric positive definite matrix. Let $\mathbf{u}$ and $\mathbf{v}$ be fixed vectors, and define $\mathbf{u}_{\delta}=\mathbf{u}+\delta \mathbf{v}$. For $j$ a positive integer, let $\tilde{g}_{j}(\delta)$ be defined by

$$
\tilde{g}_{j}(\delta)=\frac{1}{2} \mathbf{e}_{1}^{T} T_{\delta}^{j} \mathbf{e}_{1}\left\|\mathbf{u}_{\delta}\right\|_{2}^{2}
$$

where $T_{\delta}$ is the Jacobi matrix produced by the symmetric Lanczos iteration applied to $A$ with starting vector $\mathbf{u}_{\delta}$. Then, for some $\eta$ satisfying $0<\eta<\delta$,

$$
\begin{align*}
\frac{\tilde{g}_{j}(\delta)-\tilde{g}_{j}(-\delta)}{2 \delta}= & \mathbf{u}^{T} A^{j} \mathbf{v}+ \\
& \sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T^{k} X^{T}-X^{T} A^{k}\right]^{\prime} \mathbf{r} \mathbf{e}_{K}^{T} T^{j-k-1} \mathbf{e}_{1} \mathbf{u}^{T} \mathbf{u}+  \tag{2.8}\\
& \left.\frac{\delta^{2}}{6}\left[\sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}\right]^{\prime \prime}\right|_{\delta=\eta}
\end{align*}
$$

Proof. See Appendix A.1.
The following corollary summarizes the integrands for which Gaussian quadrature is exact.

Corollary 2.2. Under the assumptions of the lemma,

$$
\frac{\tilde{g}_{j}(\delta)-\tilde{g}_{j}(-\delta)}{2 \delta}=\mathbf{u}^{T} A^{j} \mathbf{v}
$$

for $0 \leq j<2 K$.
Lemma 2.1 can be used to show consistency of the computed solution with $e^{-L_{N} t} \mathbf{f}_{N}$, but we need to show consistency with the exact solution of the underlying PDE, $u(x, t)=$ $e^{-L t} f(x)$. Therefore, we need the following result to relate the discrete inner products employed by Algorithm 2.1 to the continuous inner products that describe the frequency components of $u(x, t)$. Recall the definition of $V_{N}$ from the beginning of Section 2.2.

Lemma 2.3. Let $f \in V_{N}$ and $L$ be an $m$-th order differential operator of the form (1.1) such that the coefficients $p$ and $q$ belong to $V_{N}$. Then $L f \in V_{2 N}$ and

$$
\begin{equation*}
\left\langle\hat{e}_{\omega}, L f\right\rangle=\hat{\mathbf{e}}_{\omega}^{T} L_{M} \mathbf{f}_{M}, \quad \omega=-M / 2+1, \ldots, M / 2-1 \tag{2.9}
\end{equation*}
$$

for $M=2^{j} N$, where $j$ is a positive integer.
Proof. See Appendix A.2.
We can now bound the local truncation error in each Fourier component of the computed solution.

THEOREM 2.4. Let $L$ be a self-adjoint $m$-th order positive definite differential operator with coefficients in $V_{N}$, and let $f(x) \in V_{N}$. Then Algorithm 2.2 is consistent; i.e.

$$
\left\langle\hat{e}_{\omega}, \tilde{S}(\Delta t, \Delta x ; f)-\exp [-L \Delta t] f\right\rangle=O\left(\Delta t^{2 K}\right)
$$

for $\omega=-N / 2+1, \ldots, N / 2-1$.
Proof. Let $\tilde{g}(\delta)$ be the function from Lemma 2.1 with $A=L_{M_{K}}, \mathbf{u}=\mathbf{c}_{\omega}$ and $\mathbf{v}=\mathbf{f}$. Furthermore, denote the entries of $T_{\delta}$ by

$$
T_{\delta}=\left[\begin{array}{ccccc}
\alpha_{1}(\delta) & \beta_{1}(\delta) & & & \\
\beta_{1}(\delta) & \alpha_{2}(\delta) & \beta_{2}(\delta) & & \\
& \ddots & \ddots & \ddots & \\
& & \beta_{K-2}(\delta) & \alpha_{K-1}(\delta) & \beta_{K-1}(\delta) \\
& & & \beta_{K-1}(\delta) & \alpha_{K}(\delta)
\end{array}\right]
$$

Finally, let $\beta_{0}(\delta)=\left\|\mathbf{u}_{\delta}\right\|_{2}$ and $\beta_{K}(\delta)=\left\|\mathbf{r}_{\delta}\right\|_{2}$. Then, by Lemmas 2.1 and 2.3,

$$
\begin{aligned}
\left\langle\hat{c}_{\omega}, u(\cdot, \Delta t)\right\rangle-c_{\omega}= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left\{\left\langle\hat{c}_{\omega}, L^{j} f\right\rangle-\frac{\tilde{g}_{j}(\delta)-\tilde{g}_{j}(-\delta)}{2 \delta}\right\} \\
= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left\{\left\langle\hat{c}_{\omega}, L^{j} f\right\rangle-\mathbf{c}_{\omega}^{T} L_{M_{K}}^{j} \mathbf{f}+\right. \\
& \left.\left.\sum_{k=K}^{j-K} \mathbf{e}_{1}^{T} \frac{d}{d \delta}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} L_{M_{K}}^{k}\right]\right|_{\delta=0} \mathbf{r e}_{K}^{T} T^{j-k-1} \mathbf{e}_{1}\right\}+ \\
& O\left(\delta \Delta t^{2 K}\right) \\
= & \left.\frac{\Delta t^{2 K}}{(2 K)!} \mathbf{e}_{1}^{T} \frac{d}{d \delta}\left[T_{\delta}^{K} X_{\delta}^{T}-X_{\delta}^{T} L_{M_{K}}^{K}\right]\right|_{\delta=0} \mathbf{r e}_{K}^{T} T^{K-1} \mathbf{e}_{1}+ \\
= & \left.\frac{\Delta\left(\delta \Delta t^{2 K}\right)}{(2 K)!} \mathbf{e}_{1}^{T} \frac{d}{d \delta}\left[\sum_{j=0}^{K-1} T_{\delta}^{j} \mathbf{e}_{K} \mathbf{r}_{\delta}^{T} L_{M_{K}}^{K-j-1}\right]\right|_{\delta=0} \mathbf{r e}_{K}^{T} T^{K-1} \mathbf{e}_{1}+ \\
& O\left(\delta \Delta t^{2 K}\right) \\
= & \left.\frac{\Delta t^{2 K}}{(2 K)!} \mathbf{e}_{1}^{T} \frac{d}{d \delta}\left[T_{\delta}^{K-1} \mathbf{e}_{K} \mathbf{r}_{\delta}^{T}\right]\right|_{\delta=0} \mathbf{r e}_{K}^{T} T^{K-1} \mathbf{e}_{1}+O\left(\delta \Delta t^{2 K}\right) \\
= & \left.\frac{1}{2} \frac{\Delta t^{2 K}}{(2 K)!} \frac{d}{d \delta}\left[\left\|\mathbf{r}_{\delta}\right\| \mathbf{e}_{1}^{T} T_{\delta}^{K-1} \mathbf{e}_{K}\right]^{2}\right|_{\delta=0}+O\left(\delta \Delta t^{2 K}\right) \\
= & \left.\frac{1}{2} \frac{\Delta t^{2 K}}{(2 K)!} \frac{d}{d \delta}\left(\beta_{0}(\delta) \cdots \beta_{K}(\delta)\right)^{2}\right|_{\delta=0}+O\left(\delta \Delta t^{2 K}\right) \\
= & O\left(\Delta t^{2 K}\right)
\end{aligned}
$$

A similar argument applies to $\left\langle\hat{s}_{\omega}, u(\cdot, \Delta t)\right\rangle-s_{\omega}$.
The preceding result indicates that even if low-dimensional Krylov subspaces are used to approximate each component of the solution, high-order temporal accuracy can be obtained.

On the other hand, it is important to note that the spatial error depends heavily on the smoothness of the coefficients of the operator $L$, as well as the initial data $f(x)$. The following result quantifies the effect of the smoothness of the coefficients.

TheOrem 2.5. Let $p(x)>0$ and $q(x) \geq 0$ belong to $V_{N}$, and let

$$
\bar{p}=\operatorname{Avg} p=\frac{1}{2 \pi} \int_{0}^{2 \pi} p(x) d x, \quad \bar{q}=\operatorname{Avg} q
$$

Let $L$ be defined as in (1.1), and assume that, $L=C+V$, where

$$
C=-\bar{p} \partial_{x x}+\bar{q} .
$$

Let $\phi_{\omega}(x)=\frac{1}{\sqrt{2 \pi}} e^{i \omega x}$, and let $\tilde{I}_{\omega}(\Delta t)$ be the approximation of

$$
I_{\omega}(\Delta t)=\left\langle\phi_{\omega}, e^{-L \Delta t} \phi_{\omega}\right\rangle
$$

computed using Algorithm 2.1 with an $N$-point grid of the form (2.1) and $K$ Gaussian quadrature nodes. Then, for $|\omega|<N / 2$,

$$
I_{\omega}(\Delta t)-\tilde{I}_{\omega}(\Delta t)=O\left(\Delta t^{2 K}\left\|V_{M_{K}}\right\|\right)
$$

Proof. See Appendix A.3.
Note that this result implies that Krylov subspace spectral methods reduce to the Fourier method in the case where $L$ has constant coefficients.
2.3.2. Stability. We now examine the stability of this time-stepping algorithm. For simplicity, we only consider the case where the $K=1$; that is, we are using a one-node Gaussian rule for each Fourier component.

THEOREM 2.6. Let the differential operators $L, C$ and $V$ be defined as in Theorem 2.5, and let $f \in V_{N}$. Let $K=1$ in Algorithm 2.2, and assume that the algorithm uses only the bounds obtained from Algorithm 2.1 by Gaussian quadrature. Then, in the limit as $\delta \rightarrow 0$, the approximate solution $\tilde{S}(\Delta t, \Delta x ; f)$ to (1.2), (1.3), (1.4) computed by one time step in Algorithm 2.2 is given by

$$
\tilde{S}(\Delta t, \Delta x ; f)=e^{-C \Delta t} P_{N}(I-\Delta t V) f
$$

where $P_{N}$ is the orthogonal projection onto $V_{N}$.
Proof. We use the notation of Algorithm 2.2. First, we note that

$$
\begin{equation*}
\lim _{\delta \rightarrow 0} c_{\omega}=\left.\frac{1}{2} \frac{d}{d \delta}\left[\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right)^{T}\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right) \exp \left[-\Delta t \alpha_{\omega}(\delta)\right]\right]\right|_{\delta=0} \tag{2.11}
\end{equation*}
$$

where

$$
\begin{equation*}
\alpha_{\omega}(\delta)=\frac{\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right)^{T} L_{M_{1}}\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right)}{\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right)^{T}\left(\hat{\mathbf{c}}_{\omega}+\delta \mathbf{u}_{n}\right)} \tag{2.12}
\end{equation*}
$$

A similar statement applies to $s_{\omega}$ and $\hat{\mathbf{u}}_{0}^{n+1}$. The result then follows from a von Neumann stability analysis of the approximate solution obtained from the limits of $c_{\omega}, s_{\omega}$ and $\hat{\mathbf{u}}_{0}^{n+1}$ as $\delta \rightarrow 0$, which can be computed by differentiating expressions such as (2.11) and (2.12) analytically.

Because $V \equiv 0$ when the operator $L$ has constant coefficients, the preceding theorem indicates that stability is dependent on the variation in the coefficients, not their magnitude, as is the case with explicit finite-difference methods. In fact, it can be shown that, if the coefficients of $L$ are sufficiently smooth, then Algorithm 2.2, under the assumptions of the theorem, is stable regardless of the time step $\Delta t$. Stability will be discussed further in an analysis that will be presented in [13].
2.3.3. Convergence. We are now ready to state and prove the principal result of this paper. As with the Lax-Richtmyer Equivalence Theorem for finite-difference methods, the consistency and stability of Algorithm 2.2 can be used to prove that it is also convergent.

THEOREM 2.7. Let $u(x, t)$ be the solution of (1.2), (1.3), (1.4), where $L$ is a self-adjoint positive definite differential operator with coefficients in $V_{N}$ and the initial data $f(x)$ belongs to $V_{N}$. Let the differential operators $C$ and $V$ be defined as in Theorem 2.5. Furthermore, assume that the Fourier coefficients $\{\hat{u}(\omega, \Delta t)\}$ of $u(x, \Delta t)=\exp [-L \Delta t] f(x)$ satisfy an estimate

$$
|\hat{u}(\omega, \Delta t)| \leq \frac{C}{|\omega|^{M}}, \quad \omega \neq 0, \quad 0 \leq \Delta t \leq t_{\text {final }}, \quad M>1
$$

Let $\tilde{u}\left(x, t_{\text {final }}\right)$ be the approximate solution computed by Algorithm 2.2. If

$$
\lim _{\Delta x, \Delta t \rightarrow 0} \frac{\Delta x^{M-1}}{\Delta t}=0, \quad \Delta x=\frac{2 \pi}{N}
$$

and $\Delta t$ satisfies

$$
\begin{equation*}
\left\|e^{-C \Delta t} P_{N}(I-\Delta t V) P_{N}\right\|_{L^{2}}<1 \tag{2.13}
\end{equation*}
$$

then Algorithm 2.2, in conjunction with Algorithm 2.1 using $K=1$ Gaussian quadrature nodes, is convergent; i.e.

$$
\lim _{\Delta x, \Delta t \rightarrow 0}\left\|\tilde{u}\left(\cdot, t_{\text {final }}\right)-u\left(\cdot, t_{\text {final }}\right)\right\|=0
$$

Proof. Let $e_{n}(x)=\tilde{u}\left(x, t_{n}\right)-u\left(x, t_{n}\right)$. If we choose the parameter $\delta$ sufficiently small in Algorithm 2.2, then it follows from Theorems 2.4 and 2.6 that

$$
\begin{aligned}
\left\|e_{n+1}\right\|= & \left\|\tilde{u}\left(\cdot, t_{n+1}\right)-u\left(\cdot, t_{n+1}\right)\right\| \\
= & \left\|\tilde{S}\left(\Delta t, \Delta x ; \tilde{u}\left(\cdot, t_{n}\right)\right)-\exp [-L \Delta t] u\left(\cdot, t_{n}\right)\right\| \\
\leq & \left\|\tilde{S}\left(\Delta t, \Delta x ; \tilde{u}\left(\cdot, t_{n}\right)\right)-\tilde{S}\left(\Delta t, \Delta x ; u\left(\cdot, t_{n}\right)\right)\right\|+ \\
& \left\|\tilde{S}\left(\Delta t, \Delta x ; u\left(\cdot, t_{n}\right)\right)-\exp [-L \Delta t] u\left(\cdot, t_{n}\right)\right\| \\
& <\left\|e_{n}\right\|+C_{1} \Delta t^{2}+C_{2} \Delta x^{M-1}
\end{aligned}
$$

where the constants $C_{1}$ and $C_{2}$ are independent of $\Delta x$ and $\Delta t$. We conclude that

$$
\left\|e_{n}\right\|<n\left(C_{1} \Delta t^{2}+C_{2} \Delta x^{M-1}\right)<\frac{t_{\text {final }}}{\Delta t}\left(C_{1} \Delta t^{2}+C_{2} \Delta x^{M-1}\right)
$$

which tends to zero as $\Delta t, \Delta x \rightarrow 0$ under the given assumptions.
It is important to note that because $L$ is positive definite, it is always possible to find $\Delta t>0$ so that the stability condition (2.13) holds.
2.4. Practical Implementation. A companion paper [12] discusses practical implementation of Algorithms 2.1 and 2.2 in detail, but we highlight the main implementation issues here.
2.4.1. Parameter Selection. We now discuss how one can select two key parameters in the algorithm: the number of quadrature nodes $K$ and the time step $\Delta t$. While it is obviously desirable to use a larger number of quadrature nodes, various difficulties can arise in addition to the expected computational expense of additional Lanczos iterations. As is well
known, the Lanczos method suffers from loss of orthogonality of the Lanczos vectors, and this vulnerability increases with the number of iterations since it tends to occur as Ritz pairs converge to eigenpairs (for details see [4]).

In order to choose an appropriate time step $\Delta t$, one can compute components of the solution using a Gaussian quadrature rule, and then extend the rule to a Gauss-Radau rule and compare the approximations, selecting a smaller $\Delta t$ if the error is too large relative to the norm of the data. Alternatively, one can use the Gaussian rule to construct a Gauss-Kronrod rule and obtain a second approximation; for details see [2]. However, it is useful to note that the time step only plays a role in the last stage of the computation of each component of the solution. It follows that one can easily construct a representation of the solution that can be evaluated at any time, thus allowing a residual $\partial u / \partial t+L u$ to be computed. This aspect of our algorithm is fully exploited in [12].

By estimating the error in each component, one can avoid unnecessary construction of quadrature rules. For example, suppose that a timestep $\Delta t$ has been selected, and the approximate solution $\tilde{u}(x, \Delta t)$ has been computed using Algorithm 2.2. Before using this approximate solution to construct the quadrature rules for the next time step, we can determine whether the rules constructed using the initial data $f(x)$ can be used to compute any of the components of $\tilde{u}(x, 2 \Delta t)$ by evaluating the integrand at time $2 \Delta t$ instead of $\Delta t$. If so, then there is no need to construct new quadrature rules for these components. This idea is explored further in [12].
2.4.2. Improving Performance. Theorem 2.6 implies that Algorithm 2.2 yields greater accuracy if the coefficients of $L$ are smoother. Therefore, it is advisable to use similarity transformations to "precondition" $L$ so that it more closely resembles a constant-coefficient operator. Some unitary similarity transformations that can be used for this purpose will be discussed in [11].

It is easy to see that a straightforward implementation of Algorithm 2.2 is prohibitively expensive, as it employs the Lanczos algorithm $O(N)$ times per time step, with each application requiring at least $O(N)$ operations. This complexity can be reduced to $O(N)$ by exploiting the fact that the matrix $L_{N}$ represents a differential operator, and that the initial vectors can be parametrized using the wave number. A practical implementation of Algorithm 2.2 can be found in [12].

The fact that the time step plays a limited role in the computation, and, in particular, is not used to construct the quadrature rules, implies that the computed components can easily be represented as simple continuous functions of $t$ without using interpolation. The availability of such a representation is exploited in [12] to obtain an even more efficient algorithm. This representation can also be differentiated analytically with respect to $t$, which is also exploited in [12] to construct a straightforward procedure for deferred correction.
3. Numerical Results. In this section we will display numerical results comparing the performance of Krylov subspace spectral methods with that of other numerical methods for problems of the form (1.2) as well as for more general problems.
3.1. Construction of Test Cases. In many of the following experiments, it is necessary to construct functions of a given smoothness. To that end, we rely on the following result (see [7]):

THEOREM 3.1. (GUSTAFSSON, KREISS, OLIGER) Let $f(x)$ be a $2 \pi$-periodic function and assume that its pth derivative is a piecewise $C^{1}$ function. Then,

$$
\begin{equation*}
|\hat{f}(\omega)| \leq \operatorname{constant} /\left(|\omega|^{p+1}+1\right) \tag{3.1}
\end{equation*}
$$

Based on this result, the construction of a $C^{p+1}$ function $f(x)$ proceeds as follows:

1. For each $\omega=1, \ldots, N / 2-1$, choose the discrete Fourier coefficient $\hat{f}(\omega)$ by setting $\hat{f}(\omega)=(u+i v) /\left|\omega^{p+1}+1\right|$, where $u$ and $v$ are random numbers uniformly distributed on the interval $(0,1)$.
2. For each $\omega=1, \ldots, N / 2-1$, set $\hat{f}(-\omega)=\overline{\hat{f}(\omega)}$.
3. Set $\hat{f}(0)$ equal to any real number.
4. Set $f(x)=\frac{1}{\sqrt{2 \pi}} \sum_{|\omega|<N / 2} \hat{f}(\omega) e^{i \omega x}$.

In the following test cases, coefficients and initial data are constructed so that their third derivatives are piecewise $C^{1}$, unless otherwise noted.

We will now introduce some differential operators and functions that will be used in a number of the experiments described in this section. As most of these functions and operators are randomly generated, we will denote by $R_{1}, R_{2}, \ldots$ the sequence of random numbers obtained using MATLAB's random number generator rand after setting the generator to its initial state. These numbers are uniformly distributed on the interval $(0,1)$.

- We will make use of a two-parameter family of functions defined on the interval $[0,2 \pi]$. First, we define

$$
f_{j, k}^{0}(x)=\operatorname{Re}\left\{\sum_{|\omega|<N / 2, \omega \neq 0} \hat{f}_{j}(\omega)(1+|\omega|)^{k+1} e^{i \omega x}\right\}, \quad j, k=0,1, \ldots,
$$

where

$$
\hat{f}_{j}(\omega)=R_{j N+2(\omega+N / 2)-1}+i R_{j N+2(\omega+N / 2)}
$$

The parameter $j$ indicates how many functions have been generated in this fashion since setting MATLAB's random number generator to its initial state, and the parameter $k$ indicates how smooth the function is. Figure 3.1 shows selected functions from this collection.
In many cases, it is necessary to ensure that a function is positive or negative, so we define the translation operators $E^{+}$and $E^{-}$by

$$
\begin{align*}
& E^{+} f(x)=f(x)-\min _{x \in[0,2 \pi]} f(x)+1  \tag{3.2}\\
& E^{-} f(x)=f(x)-\max _{x \in[0,2 \pi]} f(x)-1 \tag{3.3}
\end{align*}
$$

- Some experiments will involve the one-parameter family of randomly generated self-adjoint differential operators

$$
L_{k}=\partial_{x}\left(E^{-} f_{0, k} \partial_{x}\right)+E^{+} f_{1, k}, \quad k=0,1, \ldots
$$

where the operators $E^{+}$and $E^{-}$were defined in (3.2), (3.3).
Many of the experiments described in this section are intended to illustrate the convergence behavior of Algorithm 2.2, with certain variations, on various problems.
3.2. Parabolic Problems. For our first example, we will solve the problem

$$
\begin{gather*}
\frac{\partial u}{\partial t}(x, t)+L_{3} u(x, t)=0, \quad 0<x<2 \pi, \quad t>0  \tag{3.4}\\
u(x, 0)=E^{+} f_{0,3}(x), \quad 0<x<2 \pi \tag{3.5}
\end{gather*}
$$

FIG. 3.1. Functions from the collection $f_{j, k}(x)$, for selected values of $j$ and $k$.

$$
\begin{equation*}
u(x, t)=u(x+2 \pi, t), \quad t>0 \tag{3.6}
\end{equation*}
$$

using the following methods:

- The Crank-Nicolson method with central differencing
- Algorithm 2.2, with 2 nodes determined by Gaussian quadrature
- Algorithm 2.2, with 2 nodes determined by Gaussian quadrature and one additional prescribed node. The prescribed node is obtained by estimating the smallest eigenvalue of $L$ using the symmetric Lanczos algorithm.
In all cases, $N=64$ gridpoints are used. For $j=0, \ldots, 6$, we compute an approximate solution $u^{(j)}(x, t)$ at $t=1$, using $\Delta t=2^{-j}$. Figure 3.2 shows estimates of the relative error in $u^{(j)}(x, 1)$ for $j=0, \ldots, 5$. Note the significant benefit of the prescribed node in the Gauss-Radau rule.
3.2.1. Varying Spatial Resolution. In Figure 3.3 we illustrate the benefit of using component-specific Krylov subspace approximations. We solve the problem (3.4), (3.5), (3.6) using the following methods:
- A two-stage, third-order scheme described by Hochbruck and Lubich in [8] for solving systems of the form $\mathbf{y}^{\prime}=A \mathbf{y}+\mathbf{b}$, where, in this case, $\mathbf{b}=0$ and $A$ is an $N \times N$ matrix that discretizes the operator $L_{3}$. The scheme involves multiplication of vectors by $\varphi(\gamma h A)$, where $\gamma$ is a parameter (chosen to be $\frac{1}{2}$ ), $h$ is the step size, and $\varphi(z)=\left(e^{z}-1\right) / z$. The computation of $\varphi(\gamma h A) \mathbf{v}$, for a given vector $\mathbf{v}$, is accomplished by applying the Lanczos iteration to $A$ with initial vector $\mathbf{v}$ to obtain

FIG. 3.2. Estimates of relative error in the computed solution $\tilde{u}(x, t)$ of (3.4), (3.5), (3.6) at $t=1$. Solutions are computed using finite differences with Crank-Nicolson (solid curve), Algorithm 2.2 with Gaussian quadrature (dashed curve), and Algorithm 2.2 with Gauss-Radau quadrature (dotted-dashed curve) with various time steps and $N=64$ grid points.
an approximation to $\varphi(\gamma h A) \mathbf{v}$ that belongs to the $m$-dimensional Krylov subspace $\mathcal{K}(A, \mathbf{v}, m)=\operatorname{span}\left\{\mathbf{v}, A \mathbf{v}, A^{2} \mathbf{v}, \ldots, A^{m-1} \mathbf{v}\right\}$.

- Algorithm 2.2, with $m$ nodes determined by Gaussian quadrature and one additional prescribed node. The prescribed node is obtained by estimating the smallest eigenvalue of $L$ using the symmetric Lanczos algorithm.
We choose $m=2$ in both cases, so that both algorithms perform the same number of matrixvector multiplications during each time step. Note that, as $N$ increases from 64 to 128 , there is no impact on the accuracy of Algorithm 2.2; the curves corresponding to this method are virtually indistinguishable. On the other hand, this increase, which results in a stiffer system, reduces the time step at which the method from [8] begins to show reasonable accuracy.

This loss of accuracy can be explained by observing that for each component of the solution, a Krylov subspace spectral method implicitly constructs a polynomial $p(\lambda)$ that interpolates $e^{-\lambda \Delta t}$ for some $\Delta t$. The interpolation points are chosen in order to maximize the degree of a quadrature rule that is used to integrate $p(\lambda)$ with respect to the componentdependent measure $\alpha(\lambda)$ defined in (2.5). It is in this sense that the approximation of each component is optimal for that component.

The method from [8] effectively uses the same polynomial approximation of $e^{-\lambda \Delta t}$ for all components, resulting in a lower degree of accuracy. If the initial data is smooth, then this uniform approximation is still very accurate for computing low-frequency components of the solution, but as $N$ increases, the computed solution includes more (erroneous) high-frequency components.
3.2.2. Convergence of Derivatives. Figure 3.4 shows the accuracy in each frequency component of the computed solution using various methods. This accuracy is measured by computing the relative difference in the first and second derivatives of approximate solutions

FIG. 3.3. Estimates of relative error in the computed solution $\tilde{u}(x, t)$ of (3.4), (3.5), (3.6) at $t=1$. Solutions are computed using the third-order method of Hochbruck and Lubich described in [8] using a Krylov subspace of dimension $m=3$ (solid curve), and Algorithm 2.2 with a 2-point Gauss-Radau rule (dashed curve) with various time steps and $N=64$ grid points (top plot) or $N=128$ grid points (bottom plot).
$\tilde{\mathbf{u}}_{j}$ and $\tilde{\mathbf{u}}_{j-1}$ to the problem (3.4), (3.5), (3.6). Each approximate solution $\tilde{\mathbf{u}}_{j}$ is computed using $\Delta t=2^{-j}$, for $j=0, \ldots, 6$, and $N=64$ gridpoints. In other words, we are measuring the error in $\mathbf{u}_{j}$ using the $H^{1}$ and $H^{2}$ seminorms (see [9]), where

$$
\begin{equation*}
\|u\|_{H^{r}}^{2}=\int_{0}^{2 \pi}\left|u^{(r)}(x)\right| d x \tag{3.7}
\end{equation*}
$$

The methods used for the comparison are Crank-Nicholson with finite differencing, backward Euler with the Fourier method, and Gauss-Radau quadrature with two Gaussian quadrature nodes. As can easily be seen, Gauss-Radau quadrature provides more rapid convergence for both higher- and lower-frequency components than the other two methods. Gaussian quadrature with no prescribed nodes does not perform as well, since the lower bounds that it yields for each integral are not as sharp as the upper bounds obtained via Gauss-Radau quadrature.
3.3. Non-Self-Adjoint Problems. While the development of our algorithm relied on the assumption that $L$ was self-adjoint, it can be shown that it works quite well in cases where $L$ is not self-adjoint. In [5], Goodman, Hou and Tadmor study the stability of the unsmoothed Fourier method when applied to the problem

$$
\begin{equation*}
\frac{\partial u}{\partial t}(x, t)-\frac{\partial}{\partial x}(\sin (x) u(x, t))=0, \quad 0<x<2 \pi, \quad t>0 \tag{3.8}
\end{equation*}
$$

FIG. 3.4. Relative error estimates in first and second derivatives of approximate solutions to (3.4), (3.5), (3.6), measured using the $H^{1}$ and $H^{2}$ seminorms, respectively. In all cases $N=64$ gridpoints are used.

$$
\begin{gather*}
u(x, 0)=\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2-1} e^{i \omega x} i \omega^{-3}, \quad 0<x<2 \pi  \tag{3.9}\\
u(x, t)=u(x+2 \pi, t), \quad t>0 \tag{3.10}
\end{gather*}
$$

Figure 3.5 compares the Fourier coefficients obtained using the Fourier method with those obtained using Gauss-Radau quadrature as in Algorithm 2.2. It is easy to see that using Algorithm 2.2 avoids the weak instability exhibited by the unsmoothed Fourier method. As noted in [5], this weak instability can be overcome by using a sufficiently large number of gridpoints, or by applying filtering techniques (see [1]) to remove high-frequency components that are contaminated by aliasing. Algorithm 2.2, by computing each Fourier component using an approximation to the solution operator that is tailored to that component, provides the benefit of smoothing, without the loss of resolution associated with filtering.

While the theory presented and cited in Section 2 is not applicable to the non-self-adjoint case, a plausible explanation can be given as to why Gaussian quadrature methods can still be employed for such problems. Each component of the solution is computed by approximating quantities of the form

$$
f(\mathbf{u})=\mathbf{u}^{T} \exp [-A \Delta t] \mathbf{u}
$$

where $\mathbf{u}$ is an $N$-vector $A$ is an $N \times N$ matrix that may or may not be symmetric. The
approximation $\tilde{f}(\mathbf{u})$ of $f(\mathbf{u})$ takes the form

$$
\tilde{f}(\mathbf{u})=\mathbf{u}^{T}\left[\sum_{j=0}^{J} w_{j} e^{-\lambda_{j} \Delta t} A^{j} \mathbf{u}\right]=\mathbf{u}^{T} P_{J}(A) \mathbf{u}
$$

and satisfies

$$
f(\mathbf{u})-\tilde{f}(\mathbf{u})=\mathbf{u}^{T}\left(\sum_{k=2 J}^{\infty}(-1)^{k} \frac{\Delta t^{k}}{k!} A^{k}\right) \mathbf{u}
$$

due to the construction of the two sets of Lanczos vectors generated by the unsymmetric Lanczos iteration. In this sense, the high accuracy of Gaussian quadrature generalizes to the non-self-adjoint case. Each quantity $f(\mathbf{u})$ can be viewed as an Riemann-Stieltjes integral over a contour in the complex plane; the use of Gaussian quadrature to evaluate such integrals is discussed in [14].

It should be noted, however, that instability can still occur if the integrals are not computed with sufficient accuracy. Unlike the weak instability that occurs in the Fourier method, the remedy is not to use more gridpoints, but to ensure that the same components are computed with greater accuracy. This can be accomplished by choosing a smaller timestep or increasing the number of quadrature nodes, and both tactics have been successful with (3.8), (3.9) in practice.
4. Generalizations. This paper has focused primarily on the applicability of Krylov subspace spectral methods to the diffusion equation in one space dimension with periodic boundary conditions. However, as illustrated in the previous section, they are well suited to many other categories of problems, which we enumerate here.

1. Problems in higher space dimension: In [10] numerical results are presented for first-order wave equations and diffusion equations in two space dimensions, as well as discussion on how to use Krylov subspace spectral methods in any number of space dimensions.
2. Non-periodic boundary conditions: In [6] Krylov subspace spectral methods are applied to a problem with Dirichlet boundary conditions. More general discussion of other boundary conditions is contained in [10].
3. Second-order wave equations: Problems that contain higher-order derivatives in time, can be solved using Krylov subspace spectral methods very easily, because the computed solutions can be differentiated analytically with respect to time. This is exploited in [6] to solve the variable-speed wave equation in one space dimension. Results for two and three dimensions have been obtained and will be presented in an upcoming paper.
4. Conclusions. By reconsidering the role of numerical quadrature in Galerkin methods, we have succeeded in developing a class of numerical methods for solving the problem (1.2), (1.3), (1.4) that overcome some of the difficulties that variable-coefficient problems pose for traditional spectral methods. By using a low-order Krylov subspace approximation of the solution operator for each component instead of a single higher-order Krylov subspace approximation for all components, high-order accuracy and near-unconditional stability is attained.

Future work will be devoted to realizing further benefit by exploiting two key properties of these methods: first, that they are more accurate for problems with smoother coefficients, and second, that the components of the computed solution in the basis of trial functions can

FIG. 3.5. Fourier coefficients of the approximate solution $\tilde{u}(x, 5)$ of (3.8), (3.9), (3.10) computed using the Fourier method (top graph) and Algorithm 2.2 with Gauss-Radau quadrature (bottom graph) with $N=64$ nodes and time step $\Delta t=1 / 32$.
be represented as continuous functions of $t$ that have a reasonably simple structure. One goal is to combine methods for efficiently computing approximate eigenfunctions of $L$ with Krylov subspace spectral methods to construct a continuous function that represents a highly accurate approximation of the exact solution $u(x, t)$ over as large a domain in $(x, t)$-space as possible, with less computational effort than that which traditional time-marching methods and subsequent interpolation would require. Such an approximation should yield useful insight into the nature of the exact solution as well as that of the eigensystem of $L$.

## Appendix A. Proofs.

A.1. Proof of Lemma 2.1. From $X_{\delta}^{T} X_{\delta}=I$ we obtain

$$
\begin{aligned}
\frac{d T_{\delta}^{j}}{d \delta} & =\sum_{k=0}^{j-1} T_{\delta}^{k} \frac{d\left(X_{\delta}^{T} A X_{\delta}\right)}{d \delta} T_{\delta}^{j-k-1} \\
& =\sum_{k=0}^{j-1} T_{\delta}^{k}\left[\left(X_{\delta}^{\prime}\right)^{T} A X_{\delta}+X_{\delta}^{T} A X_{\delta}^{\prime}\right] T_{\delta}^{j-k-1} \\
& =\sum_{k=0}^{j-1} T_{\delta}^{k}\left[\left(X_{\delta}^{\prime}\right)^{T}\left(X_{\delta} T_{\delta}+\mathbf{r}_{\delta} \mathbf{e}_{K}^{T}\right)+\left(\mathbf{e}_{K} \mathbf{r}_{\delta}^{T}+T_{\delta} X_{\delta}^{T}\right) X_{\delta}^{\prime}\right] T_{\delta}^{j-k-1} \\
& =\left(X_{\delta}^{\prime}\right)^{T} X_{\delta} T_{\delta}^{j}+T_{\delta}^{j} X_{\delta}^{T} X_{\delta}^{\prime}+
\end{aligned}
$$

$$
\sum_{k=0}^{j-1} T_{\delta}^{k}\left(X_{\delta}^{\prime}\right)^{T} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1}+T_{\delta}^{k} \mathbf{e}_{K} \mathbf{r}_{\delta}^{T} X_{\delta}^{\prime} T_{\delta}^{j-k-1}
$$

From symmetry, it follows that

$$
\frac{1}{2} \frac{d}{d \delta}\left(\mathbf{e}_{1}^{T} T_{\delta}^{j} \mathbf{e}_{1}\right)=\mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} X_{\delta} T_{\delta}^{j} \mathbf{e}_{1}+\sum_{k=0}^{j-1} \mathbf{e}_{1}^{T} T_{\delta}^{k}\left(X_{\delta}^{\prime}\right)^{T} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1}
$$

From repeated application of the relation $A X_{\delta}=X_{\delta} T_{\delta}+\mathbf{r}_{\delta} \mathbf{e}_{K}^{T}$, we obtain

$$
A^{j} X_{\delta}=X_{\delta} T_{\delta}^{j}+\sum_{k=0}^{j-1} A^{k} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1}
$$

which yields

$$
\begin{aligned}
\frac{1}{2} \frac{d}{d \delta}\left(\mathbf{e}_{1}^{T} T_{\delta}^{j} \mathbf{e}_{1}\right)= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} X_{\delta} T_{\delta}^{j} \mathbf{e}_{1}+\sum_{k=0}^{j-1} \mathbf{e}_{1}^{T} T_{\delta}^{k}\left(X_{\delta}^{\prime}\right)^{T} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \\
= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} A^{j} X_{\delta} \mathbf{e}_{1}+ \\
& \sum_{k=0}^{j-1} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k}\left(X_{\delta}^{\prime}\right)^{T}-\left(X_{\delta}^{\prime}\right)^{T} A^{k}\right] \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \\
= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} A^{j} X_{\delta} \mathbf{e}_{1}+ \\
& \sum_{k=0}^{j-1} \mathbf{e}_{1}^{T}\left[\left(T_{\delta}^{k}\right)^{\prime} X_{\delta}^{T}+T_{\delta}^{k}\left(X_{\delta}^{\prime}\right)^{T}-\left(X_{\delta}^{\prime}\right)^{T} A^{k}\right] \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \\
= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} A^{j} X_{\delta} \mathbf{e}_{1}+ \\
& \sum_{k=0}^{j-1} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \\
= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} A^{j} X_{\delta} \mathbf{e}_{1}+ \\
& \sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1}
\end{aligned}
$$

From the relations

$$
X_{\delta} \mathbf{e}_{1}=\frac{\mathbf{u}_{\delta}}{\left\|\mathbf{u}_{\delta}\right\|_{2}}, \quad X_{\delta}^{\prime} \mathbf{e}_{1}=\frac{1}{\left\|\mathbf{u}_{\delta}\right\|_{2}}\left(\mathbf{v}-\frac{\mathbf{u}^{T} \mathbf{v}+\delta \mathbf{v}^{T} \mathbf{v}}{\left\|\mathbf{u}_{\delta}\right\|_{2}^{2}} \mathbf{u}_{\delta}\right)
$$

we obtain

$$
\begin{aligned}
\tilde{g}_{j}^{\prime}(\delta)= & \frac{1}{2}\left[\mathbf{e}_{1}^{T} \frac{d T_{\delta}^{j}}{d \delta} \mathbf{e}_{1}\left\|\mathbf{u}_{\delta}\right\|_{2}^{2}+2 \mathbf{e}_{1}^{T} T_{\delta}^{j} \mathbf{e}_{1}\left(\mathbf{u}^{T} \mathbf{v}+\delta \mathbf{v}^{T} \mathbf{v}\right)\right] \\
= & \mathbf{e}_{1}^{T}\left(X_{\delta}^{\prime}\right)^{T} A^{j} X_{\delta} \mathbf{e}_{1} \mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}+ \\
& \sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}+ \\
& \mathbf{e}_{1}^{T} T_{\delta}^{j} \mathbf{e}_{1}\left(\mathbf{u}^{T} \mathbf{v}+\delta \mathbf{v}^{T} \mathbf{v}\right)
\end{aligned}
$$

$$
\begin{aligned}
= & \left(\mathbf{v}-\frac{\mathbf{u}^{T} \mathbf{v}+\delta \mathbf{v}^{T} \mathbf{v}}{\mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}} \mathbf{u}_{\delta}\right)^{T} A^{j} \mathbf{u}_{\delta}+ \\
& \sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}+ \\
& \mathbf{u}_{\delta}^{T} A^{j} \mathbf{u}_{\delta} \frac{\mathbf{u}^{T} \mathbf{v}+\delta \mathbf{v}^{T} \mathbf{v}}{\mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta}} \\
= & \mathbf{u}_{\delta}^{T} A^{j} \mathbf{v}+\sum_{k=K}^{j-K} \mathbf{e}_{1}^{T}\left[T_{\delta}^{k} X_{\delta}^{T}-X_{\delta}^{T} A^{k}\right]^{\prime} \mathbf{r}_{\delta} \mathbf{e}_{K}^{T} T_{\delta}^{j-k-1} \mathbf{e}_{1} \mathbf{u}_{\delta}^{T} \mathbf{u}_{\delta} .
\end{aligned}
$$

The lemma follows immediately from the Taylor expansion of $\tilde{g}_{j}(\delta)$.
A.2. Proof of Lemma 2.3. For convenience, we write

$$
L=\sum_{\alpha=0}^{m} a_{\alpha}(x)\left(\frac{\partial}{\partial x}\right)^{\alpha}
$$

where $a_{2}(x)=-p(x), a_{1}(x)=-p^{\prime}(x)$, and $a_{0}(x)=q(x)$. For $j=1$, we have

$$
\begin{aligned}
L f(x) & =\sum_{\alpha=0}^{m} a_{\alpha}(x)\left(\frac{\partial}{\partial x}\right)^{\alpha} f(x) \\
& =\sum_{\alpha=0}^{m}\left(\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2-1} \hat{a}_{\alpha}(\omega) e^{i \omega x}\right)\left(\frac{1}{\sqrt{2 \pi}} \sum_{\xi=-N / 2+1}^{N / 2-1} \hat{f}(\xi)(i \xi)^{\alpha} e^{i \xi x}\right) \\
& =\sum_{\alpha=0}^{m}\left\{\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2-1}\left[\frac{1}{\sqrt{2 \pi}} \sum_{\xi=-N / 2+1}^{N / 2-1} \hat{a}_{\alpha}(\omega) \hat{f}(\xi)(i \xi)^{\alpha} e^{i(\omega+\xi) x}\right]\right\} \\
& =\sum_{\alpha=0}^{m}\left\{\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-N / 2+1}^{N / 2-1}\left[\frac{1}{\sqrt{2 \pi}} \sum_{\eta=-N+1}^{N-1} \hat{a}_{\alpha}(\omega) \hat{f}(\eta-\omega)(i \xi)^{\alpha} e^{i \eta x}\right]\right\} \\
& =\sum_{\alpha=0}^{m}\left\{\frac{1}{\sqrt{2 \pi}} \sum_{\eta=-N+1}^{N-1} \frac{1}{\sqrt{2 \pi}}\left[\sum_{\omega=-N / 2+1}^{N / 2-1} \hat{a}_{\alpha}(\omega) \hat{f}(\eta-\omega)(i \xi)^{\alpha}\right] e^{i \eta x}\right\},
\end{aligned}
$$

thus $L f \in V_{2 N}$. Because Fourier interpolation of $L f$, for any degree $\geq 2 N$, is exact, (2.9) follows.
A.3. Proof of Theorem 2.5. Let the vector $\hat{\mathbf{e}}_{\omega}$ be a discretization of $\phi_{\omega}(x)=\frac{1}{\sqrt{2 \pi}} e^{i \omega x}$ on a uniform grid of the form (2.1); that is,

$$
\left[\hat{\mathbf{e}}_{\omega}\right]_{j}=\frac{1}{\sqrt{2 \pi}} e^{i \omega j h}, \quad j=0,1, \ldots, N-1
$$

The approximation $\tilde{I}_{\omega}(\Delta t)$ of $I_{\omega}(\Delta t)$ computed by Algorithm 2.1 has the form

$$
\tilde{I}_{\omega}(\Delta t)=\mathbf{e}_{1}^{H} e^{-T \Delta t} \mathbf{e}_{1}
$$

where $T$ is the $K \times K$ Jacobi matrix produced by the symmetric Lanczos algorithm applied to the matrix $L_{M_{K}}$ defined in (2.2) with initial vector $\hat{\mathbf{e}}_{\omega}$. Thus we have

$$
L_{M_{K}} X=X T+\mathbf{r e}_{K}^{H}, \quad X^{H} X=I_{K}, \quad X \mathbf{e}_{1}=\hat{\mathbf{e}}_{\omega}
$$

We can express the error $E_{\omega}(\Delta t)=\left\langle\phi_{\omega}, \exp [-L \Delta t] \phi_{\omega}\right\rangle-\tilde{I}_{\omega}(\Delta t)$ as

$$
\begin{aligned}
E_{\omega}(\Delta t)= & \left\langle\phi_{\omega}, \exp [-L \Delta t] \phi_{\omega}\right\rangle-\tilde{I}_{\omega}(\Delta t) \\
= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left(\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\mathbf{e}_{1}^{H} T^{j} \mathbf{e}_{1}\right) \\
= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left(\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega}+\right. \\
& \left.\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega}-\mathbf{e}_{1}^{H} X^{H} X T^{j} \mathbf{e}_{1}\right) \\
= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left(\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega}+\right. \\
& \left.\hat{\mathbf{e}}_{\omega}^{H}\left(L_{M_{K}}^{j} X-X T^{j}\right) \mathbf{e}_{1}\right) \\
= & \sum_{j=0}^{\infty} \frac{\Delta t^{j}}{j!}\left[\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega}+\right. \\
& \left.\hat{\mathbf{e}}_{\omega}^{H}\left(\sum_{k=0}^{j-1} L_{M_{K}}^{k} \mathbf{r} \mathbf{e}_{K}^{H} T^{j-k-1}\right) \mathbf{e}_{1}\right] .
\end{aligned}
$$

We first consider the expression $\mathbf{e}_{K}^{H} T^{j} \mathbf{e}_{1}$, where $j$ is a positive integer and $K>1$. Then

$$
\beta_{1}=T_{21}=\left\|V_{M_{K}} \hat{\mathbf{e}}_{\omega}\right\|_{2}
$$

It follows from the fact that $T$ is tridiagonal, that

$$
\left|\left[T^{j}\right]_{K 1}\right| \leq\left\|V_{M_{K}}\right\|\left\|3 L_{M_{K}}\right\|^{j-1}
$$

and therefore, for $0 \leq k<j-1$,

$$
\left|\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{k} \mathbf{r}\left[T^{j-k-1}\right]_{K 1}\right| \leq 3^{j-k-2}\left\|V_{M_{K}}\right\|\left\|L_{M_{K}}\right\|^{j+K-2}
$$

When $j=k-1$ and $K>1$, the expression on the left side vanishes. If $K=1$, then $T=\alpha_{1}$ and $\mathbf{r}=V_{M_{1}} \hat{\mathbf{e}}_{\omega}$, which yields a similar bound for $0 \leq k \leq j-1$.

Next, we consider the expression $E_{\omega, j}=\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega}$, where $j$ is a nonnegative integer. By Lemma 2.1, $E_{\omega, j}=0$ for $j \leq 2 K$. For $j>2 K$, we define $f_{\omega, \ell}(x)=$ $L^{\ell} \phi_{\omega}(x)$ for any nonnegative integer $\ell$. Furthermore, for even positive integers $M$ we define the following operators on the space of continuous functions defined on $[0,2 \pi]$ :

- $P_{M}$ is the orthogonal projection onto $V_{M}$ :

$$
P_{M} f(x)=\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-M / 2+1}^{M / 2-1} e^{i \omega x} \hat{f}(\omega)
$$

- $\Pi_{M}$ is the composition of $P_{M}$ and the $M$-point interpolation operator, using an $M$ point uniform grid of the form (2.1):

$$
\Pi_{M} f(x)=\frac{1}{\sqrt{2 \pi}} \sum_{\omega=-M / 2+1}^{M / 2-1} e^{i \omega x}\left(\frac{h}{\sqrt{2 \pi}} \sum_{j=0}^{M-1} e^{-i \omega 2 \pi j h} f(j h)\right)
$$

with $h=\frac{2 \pi}{M}$. Certainly, if $f \in V_{M}$, then $\Pi_{M} f=f$.

Using these definitions, we obtain

$$
\begin{aligned}
E_{\omega, j} & =\left\langle\phi_{\omega}, L^{j} \phi_{\omega}\right\rangle-\hat{\mathbf{e}}_{\omega}^{H} L_{M_{K}}^{j} \hat{\mathbf{e}}_{\omega} \\
& =\left\langle f_{\omega, K},\left[L^{j-2 K}-\left(\Pi_{M_{K}} L \Pi_{M_{K}}\right)^{j-2 K}\right] f_{\omega, K}\right\rangle \\
& =\left\langle f_{\omega, K},\left[(C+V) L^{j-2 K-1}-\Pi_{M_{K}}(C+V) \Pi_{M_{K}}\left(\Pi_{M_{K}} L \Pi_{M_{K}}\right)^{j-2 K-1}\right] f_{\omega, K}\right\rangle .
\end{aligned}
$$

Let $j=2 K+1$. By Lemma 2.1, $f_{\omega, K} \in V_{M_{K}}$, from which it follows that $C^{*} f_{\omega, K} \in V_{M_{K}}$, and therefore

$$
E_{\omega, 2 K+1}=\left\langle f_{\omega, K},\left[V-\Pi_{M_{K}} V \Pi_{M_{K}}\right] f_{\omega, K}\right\rangle
$$

from which it follows that

$$
\left|E_{\omega, 2 K+1}\right| \leq 2\left\|V_{M_{K}}\right\|\left\|L_{M_{K}}\right\|^{2 K}
$$

In general, we have

$$
\begin{aligned}
E_{\omega, j}= & \left\langle f_{\omega, K},\left[L^{j-2 K}-\left(\Pi_{M_{K}} L \Pi_{M_{K}}\right)^{j-2 K}\right] f_{\omega, K}\right\rangle \\
= & \left\langle f_{\omega, K},\left[C^{j-2 K}-\left(\Pi_{M_{K}} C \Pi_{M_{K}}\right)^{j-2 K}\right] f_{\omega, K}\right\rangle+ \\
& \left\langle f_{\omega, K},\left[E_{j-2 K}-E_{M_{K}, j-2 K}\right] f_{\omega, K}\right\rangle \\
= & \left\langle f_{\omega, K},\left[E_{j-2 K}-E_{M_{K}, j-2 K}\right] f_{\omega, K}\right\rangle
\end{aligned}
$$

where

$$
E_{j-2 K}=L^{j-2 K}-C^{j-2 K}
$$

and

$$
E_{M_{K}, j-2 K}=\left(\Pi_{M_{K}} L \Pi_{M_{K}}\right)^{j-2 K}-\left(\Pi_{M_{K}} C \Pi_{M_{K}}\right)^{j-2 K}
$$

It follows that, for fixed $\Delta t, E_{\omega}(\Delta t) \rightarrow 0$ linearly with $\left\|V_{M_{K}}\right\|$. By Lemma 2.1, the terms in (A.1) that are of order $<2 K$ in $\Delta t$ vanish, which completes the proof.
